Background: Recent randomized controlled trials have failed to show a survival difference between adjuvant chemotherapy (CT) and adjuvant chemoradiotherapy (CRT) in patients with resected gastric cancer (GC). However, a subset of patients with lymph node (LN) positive disease may still benefit from CRT. Additional evidence is needed to help guide physicians in identifying patients in whom CRT should be considered. Our objective was then to compare survival outcomes based on lymph node ratio (LNR) (ratio of metastatic to harvested LNs) for patients with gastric and gastroesophageal junction (GEJ) adenocarcinoma treated with surgery and either CT or CRT.

Methods: This retrospective population-based study used California Cancer Registry (CCR) data from 2004 to 2013. It included 1,493 patients diagnosed with stage IB–III gastric/GEJ adenocarcinoma and treated with CT or CRT following total or partial gastrectomy. Overall survival (OS) was the primary outcome and GC-specific survival was secondary. Mortality hazards ratios (HR) for these outcomes were computed using propensity score weighted Cox regression models, stratified by LNR strata categories as 0%, 1–9%, 10–25% and >25%.

Results: Out of 1,493 patients that met inclusion criteria, 462 were treated with CT while 1,031 received CRT. Median follow-up for all subjects was 76 months and median survival was 54 months for CRT and 35 for the CT cohort, $P < 0.001$. Compared to CT, CRT was associated with improved survival among patients with LNR of 10–25% [HR = 0.62 (95% CI, 0.46–0.83)] and >25% [HR = 0.67 (95% CI, 0.56–0.80)]. Similar findings were observed for GC-specific survival and for analyses limited to patients that had at least 15 LNs evaluated.

Conclusions: LNR appears to be a simple and readily available measure that could be used in treatment planning for resected GC. CRT offers significant survival advantage over CT among patients with high LN disease burden (LNR of $\geq 10\%$).

Introduction

Although surgery remains the mainstay of treatment for gastric cancer (GC) (1,2), a multimodal treatment approach is often required to extend survival due to a high incidence of locoregional recurrence and distant metastases after curative resection. Perioperative chemotherapy (PC) (3), adjuvant chemoradiation (CRT) (4), and adjuvant chemotherapy (CT) (5,6) have all been shown to improve survival when compared to surgery alone in randomized clinical trials. In the United States (U.S.), the Southwestern Oncology Group Intergroup trial (INT0116) was the first to show superior overall survival (OS) with adjuvant CRT compared to surgery-only among patients with resected GC [mortality hazard ratio (HR) of 0.74; 95% confidence interval (CI), 0.60–92] (4). However, this study has been heavily criticized for the surgical quality, as 54% of patients underwent D0 lymphadenectomy and only 10% had a D2 lymphadenectomy. This has limited the acceptance of adjuvant CRT outside of the U.S. with some critics interpreting the reported adjuvant CRT effect as merely compensating for inadequate surgery. Furthermore, this concern has prevailed despite results from retrospective studies that have confirmed improved survival for adjuvant CRT compared to surgery-only (7,8), even among patients who received a D2 lymphadenectomy (8).

To date, the South Korean Adjuvant Chemoradiotherapy in Stomach Tumors (ARTIST) trial is the only clinical trial that has compared adjuvant CRT to CT among GC patients treated with D2 lymphadenectomy (9). Initial results from the ARTIST trial showed no significant difference in disease free survival (DFS) for patients treated with adjuvant CRT compared to adjuvant CT, with a 3-year DFS of 78.2% versus 74.2%, $P=0.086$, respectively. However, a subgroup analysis among subjects with lymph node (LN) positive disease showed superior DFS for adjuvant CRT compared to adjuvant CT [HR 0.69 (95% CI, 0.474–0.995), $P=0.047$] (9). Follow-up analyses of the ARTIST trial data showed that superior survival with adjuvant CRT was limited to GC patients with a lymph node ratio (LNR) greater than 25% (10). These findings, however, have never been evaluated in a Western population.

The objective of this study was to use prospectively collected California Cancer Registry (CCR) data to compare survival, stratified by LNR, among resected GC patients treated with either adjuvant CRT or adjuvant CT in a Western population. This comparison has not been made in randomized clinical trials in Western populations.

Methods

Study population

The CCR is a California statewide cancer surveillance program that has been operational since 1988 and maintains data on cancer occurrence, treatment and survival (11). Using CCR data and the International Classification of Disease for Oncology, Third Edition (12) (ICD-O-3) topographic codes C160-C169, records for patients diagnosed with gastric and gastroesophageal junction (GEJ) from 2004 through 2013 were retrieved. Additionally, ICD-O-3 morphology codes M-8120-M-8240 and M-8255-M-8576 were used to select patients diagnosed with adenocarcinoma, while the American Joint Committee on Cancer Staging, 6th Edition (AJCC 6) (13) rules were used to retain stage IB–III GC cases. Patients were classified into the CT cohort if chemotherapy was initiated after surgery with no receipt of pre- or postoperative radiotherapy. Similarly, patients were selected into the CRT group if chemoradiation was initiated following surgery. This study was conducted using existing data without patient contact and was approved by Loma Linda University Institutional Review Board [59061].

Study outcomes

The primary endpoint was OS, while gastric cancer-specific survival (GCSS) was a secondary endpoint. Survival was calculated as the time from surgery to death or the last date of study follow-up (December 31, 2014), whichever came first.

Study covariates

Demographic variables included in this study were age at diagnosis, sex and race/ethnicity (Asian/other, Hispanic, non-Hispanic black, non-Hispanic white). Additionally, tumor characteristics that included T-stage (13), histology type as intestinal (M-8144), diffuse (M-8145) or signet ring histology (M-8490) (12), tumor location (proximal/distal) and cardia/GEJ location (yes/no) were included in analyses as appropriate.

Statistical analyses

Demographic and tumor characteristics were summarized using counts and percentages with comparison between treatment cohorts conducted using χ^2 tests. Median follow-

up time was estimated using the inverse Kaplan-Meier curve (14), while Kaplan-Meier survival curves with log-rank tests were used to compare median survival times. To harmonize differences in demographic and tumor characteristics observed between adjuvant CRT and adjuvant CT treatment groups, propensity scores were used in a two-step process (15). First, demographic and tumor characteristics were used in a logistic regression model to predict treatment propensity scores. In a second step, propensity score (inverse probability weighting) weighted Cox proportional hazards models were used to estimate mortality hazards ratios (HR) with 95% CI limits. Log-log plots and Schoenfeld residuals were used to assess the proportionality assumption. All tests were two-sided, performed using a significance level of five percent ($\alpha=0.05$) and conducted using SAS software, Version (9.4) of the SAS System for Windows. Copyright ©2002-2012 SAS Institute Inc.

Subgroup analyses

To evaluate the impact of positive LN disease burden on survival findings, all analyses were conducted within LNR strata. LNR is calculated as the number of positive LNs divided by the total count of all LNs examined (positive LNs/total count of nodes examined). In this study four LNR strata that include 0%, 1–9%, 10–25% and >26% as described by Marchet *et al.* (16) and adopted by the ARTIST trial were used (10). Furthermore, since dissection of at least 15 LNs is recommended for adequate staging and survival (1), separate analyses were conducted for patients that had less than 15 LNs and those with 15 or more LNs examined.

Results

Study population

Between 2004 and 2013, 18,866 patients diagnosed with gastric/GEJ adenocarcinomas were identified, including 5,806 that were stage IB-III. Among these, 4,678 patients had been treated with total or partial gastrectomy. After excluding patients who did not receive any adjuvant treatment, underwent preoperative CT or CRT, and those who had no regional LNs examined, we derived a final analytical sample of 462 patients treated with CT and 1,031 that received CRT (Figure 1). Median follow-up was 76 months.

Patient's age, sex, and tumor characteristics that include

stage, histology type, and primary tumor location were comparable between the CT and the CRT cohort (Table 1). Additionally, there were no differences in the extent of LN dissection ($P=0.12$) and the distribution of LNR categories ($P=0.87$) between the two treatment cohorts (Table 1). Of note, nearly 60% of the patients had 15 or more LN evaluated. There were ethnic differences in the type of adjuvant treatment received. Non-Hispanic whites more likely to be treated with CT (33.6% *vs.* 26.9%), while Asian/other (29.9% *vs.* 34.8%) and Hispanic (29.2% *vs.* 33.2%) were more likely to have received CRT respectively ($P=0.009$).

CRT versus CT

The median survival was 54 months for the CRT cohort versus 35 months for the CT cohort, $P<0.001$. Compared to CT, CRT was associated with longer median survival among patients with 10–25% LNR ($P=0.002$) and those with >25% LNR ($P<0.0001$) (Figure 2). No significant difference in median survival was observed between CRT and CT among patients with 0% LNR ($P=0.16$) and those with 1–9% LNR ($P=0.088$) (Figure 2). Further propensity score weighted analyses were performed for OS and GCSS for all patients, and for the subgroup of patients with ≥ 15 LN examined, and excluding patients with cardia/GEJ cancers. Among all patients, CRT was associated with improved survival compared to CT [HR 0.74 (95% CI, 0.64–0.84)]. This survival benefit was primarily seen among patients that had 10–25% LNR [HR 0.62 (95% CI, 0.46–0.83)] and those with >25% LNR [HR 0.67 (95% CI, 0.56–0.80)] (Figure 3). Comparable findings were observed for analyses that evaluated GCSS [HR 0.68 (95% CI, 0.58–0.79)]. Subgroup analysis was performed for patients with ≥ 15 LN evaluated to assess the outcome differences between treatment groups among patients who had adequate lymphadenectomy. Similar to the results observed for the entire study cohort, CRT was associated with improved all cause [HR 0.73 (95% CI, 0.61–0.88)] and GC specific mortality [HR 0.68 (95% CI, 0.55–0.84)] (Figure 3). As noted previously, this survival benefit was primarily observed among patients with $\geq 10\%$ LNR. Due to the current treatment recommendations for preoperative chemoradiation in patients with GEJ cancer, we chose to perform a subgroup analysis excluding patients with cardia/GEJ tumors. The survival differences observed for this subgroup of patients were similar to that seen in the overall study population and the subgroup of patients

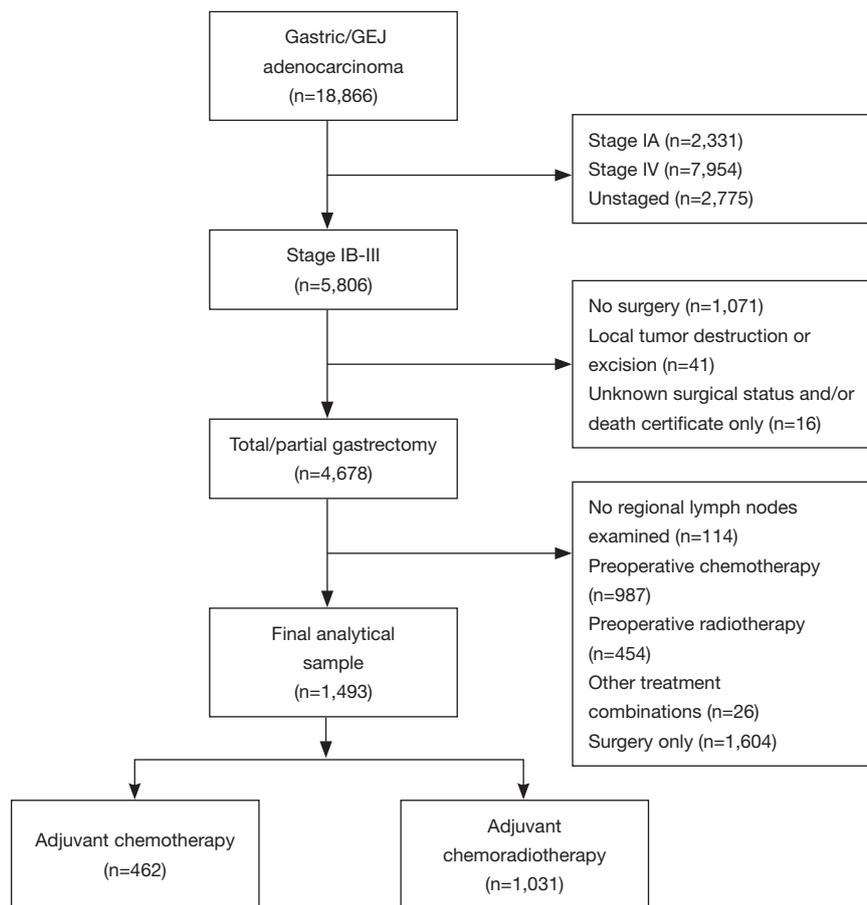

Figure 1 Patient selection. GEJ, gastroesophageal junction.

with ≥ 15 LNs evaluated (*Figure 3*).

Discussion

Our study clearly demonstrates that adjuvant CRT is associated with significantly improved survival compared to adjuvant CT in patients with resected GC who have high metastatic LN disease burden ($\geq 10\%$ LNR) (*Figure 2*). The results of our study have important therapeutic implications for GC management. The benefit of adjuvant CRT compared to adjuvant CT in patients with GC after D2 gastric resection has been questioned after the publication of the ARTIST trial results (9). The final results of this trial, published after a median follow-up of 7 years showed no significant survival benefit between patients treated with CRT *vs.* CT after D2 gastric resection. However, based on a post-hoc subgroup analyses, the authors reported that adjuvant chemoradiotherapy might be of benefit in patients

with LN positive disease, specifically those with LNR of $\geq 25\%$. Based on this finding, the ARTSIT II trial has been designed to evaluate the benefit of CRT compared to CT in patients with LN positive GC. The results of the ARTIST II trial are not expected to be available for few years. In the interim, it is important to assess the impact of LNR on the survival effects of CRT versus CT among patients treated with curative intent in a large Western population. To this end, we conducted the current study to aid clinicians in identifying patients who may benefit from CRT.

The importance of adequate LN assessment in GC has been well documented by several investigators (17). Although, the actual number of LN evaluated is important, the LNR has been shown to be more important in various cancers (18-20). Marchet *et al.* (16) reported the 5-year survival outcomes of patients who underwent adequate and inadequate lymphadenectomy, stratified based on the LNR categories (N0—0%, N1—1–9%, N2—10–25%,

CT, chemotherapy; CRT, chemoradiotherapy.

and N3—>25%). LNR ratio retained its significance as an independent prognostic factor, even among the patients who underwent inadequate lymphadenectomy. We utilized the methodology of Marchet *et al.* for LNR categorization in the current study and found that patients with ≥10% LNR have an associated survival advantage when treated with CRT compared to CT.

While we recognize that the ARTIST trial was a randomized trial, our results have important differences from that of the ARTIST trial. First, we found that CRT was associated with improved survival compared to CT among all patients, which is in contrast to the results of ARTIST trial which showed no survival differences between CRT and CT (9). This is likely due to a higher proportion of patients with LNR >25%, thus higher statistical power, in our study for both CRT (45.45%) and CT (43.55%) compared to the ARTIST trial (19.87%) (9). Second, while in the current study, CRT was associated with improved survival among patients having LNR ≥10%, the survival benefit with CRT in the ARTIST trial was limited to subjects with a LNR greater than 25% (10). This difference could possibly be due to differences in the number of LN evaluated. In the ARTIST trial, the median number of LN evaluated were 40 [13–142] for CRT and 40 [12–84] for CT while the patients in the current study had a median of 16 [1–98] LN for CRT and 17 [1–98] for CT among all subjects, and 21 [15–90] LN for CRT and 23 [15–90] for CT among patients that had at least 15 LN examined (9). These differences highlight the importance of evaluating the role of CRT compared to CT in a Western population.

While CRT is often considered as a treatment modality for reduction of local and regional recurrence among patients that received an inadequate LN dissection (4,21), we observed that the survival benefit conferred by CRT in patients with ≥10% LNR persisted even after excluding

patients who underwent inadequate LN dissection. This finding potentially addresses one of the major criticisms of the INT0116 trial. In the current study, anatomic sub-sites were identified using ICD-O-3 topographic codes that combine cardia and GEJ cases (C160). Since preoperative CRT is effective (22) and recommended (23) for GEJ tumors, we performed a subgroup analyses excluding patients with cardia/GEJ tumors. Exclusion of these patients did not significantly alter our results, indicating that our findings were not mainly dependent on the benefit of CRT in patients with GEJ cancers.

Several ongoing clinical trials are evaluating the role and timing of radiotherapy in patients with GC. Initial results of the CRITICS trial, designed to compare adjuvant CRT versus adjuvant CT among patients that received preoperative chemotherapy (24) were recently presented at the American Society of Clinical Oncology annual meeting. After a median follow-up of 50 months, the primary endpoint of 5-year survival was 41.3% for CT and 40.9% for CRT after receipt of neoadjuvant chemotherapy and adequate surgery (P=0.99) (25). The effect of LNR in this population however has not yet been examined (24,26). Other trials include the TOPGEAR trial which is assessing the effect of preoperative chemoradiotherapy compared to PC (23). The ARTIST II and CRITICS II trials are currently ongoing, as follow-up studies of the original trials among node positive patients.

Our study has significant implications to current clinical practice especially since adjuvant CRT and CT have not been compared in a clinical trial setting among Western patients who undergo upfront surgical resection. In addition, with the use of registry data containing a large number of patients with diverse demographics and well-matched cohorts, our findings are reflective of “real-world” practice in the West.

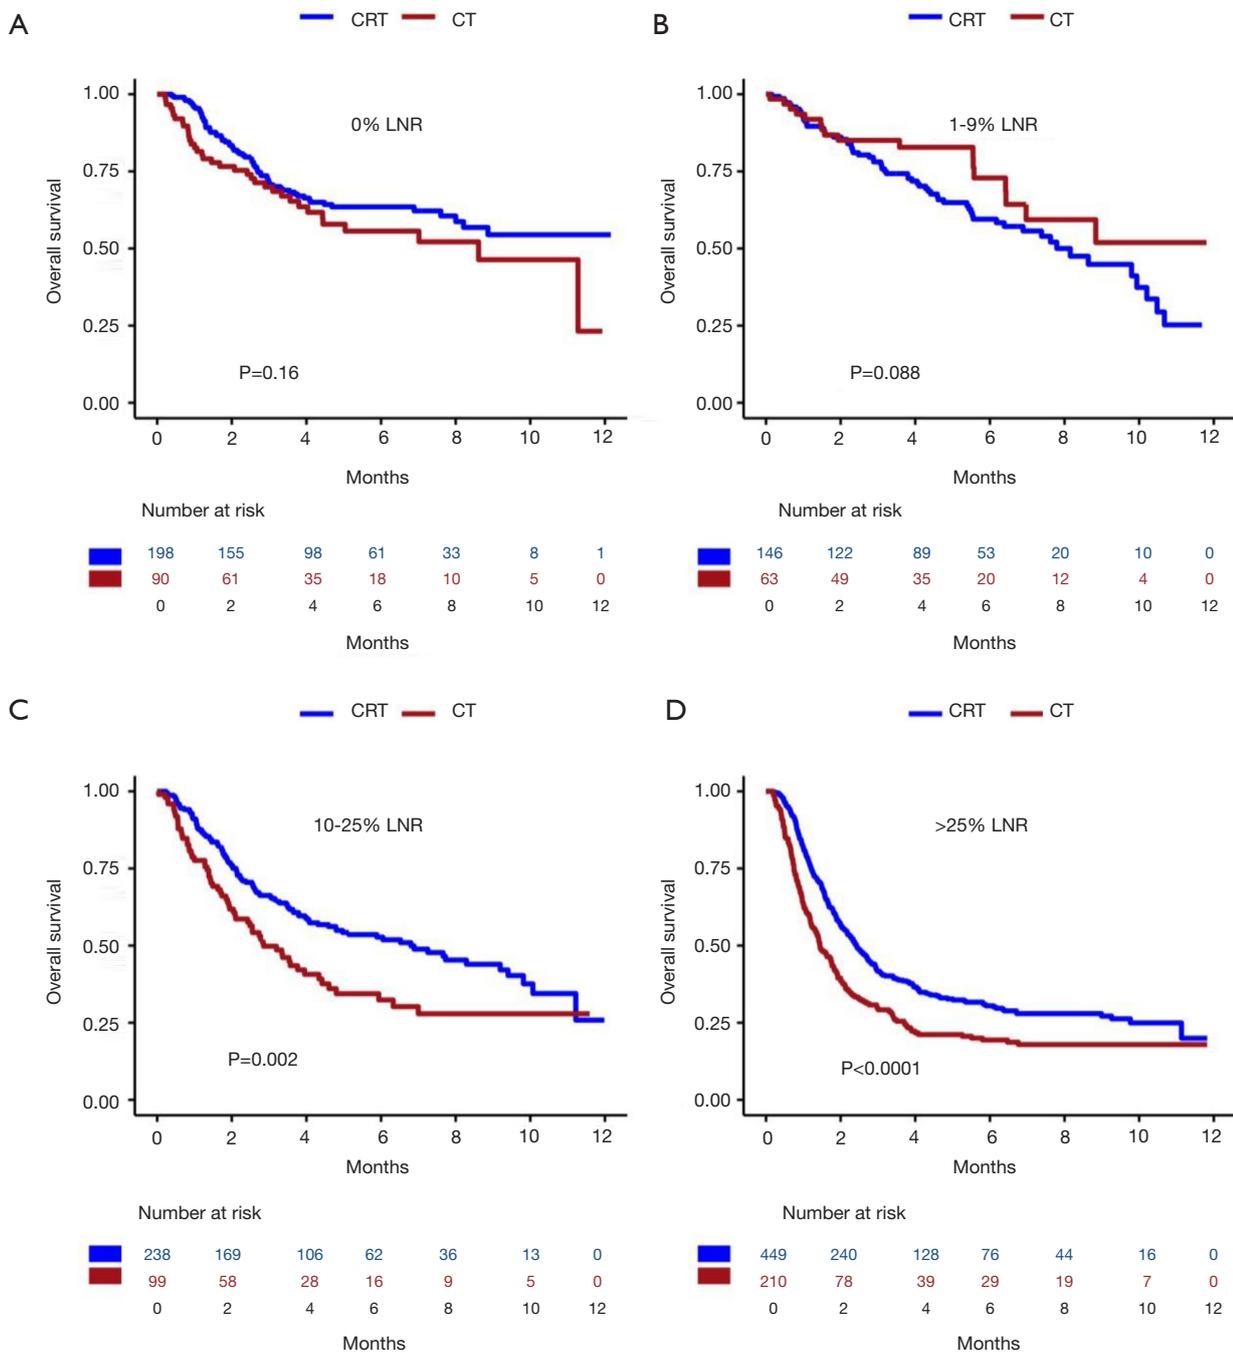

Figure 2 Kaplan-Meier survival curves for adjuvant CT and adjuvant CRT by LNR strata as 0% LNR (A), 1–9% LNR (B), 10–25% LNR (C) and >25% LNR (D). CT, chemotherapy; CRT, chemoradiotherapy; LNR, lymph node ratio.

Limitations

Our study has several limitations that are inherent to large, population-based retrospective studies. Patient comorbidities and complications of treatment are not

documented in the CCR. By design, only patients that underwent total or partial gastrectomy and started adjuvant treatment were included in this study allowing for increased homogeneity between the study cohorts and to minimize the

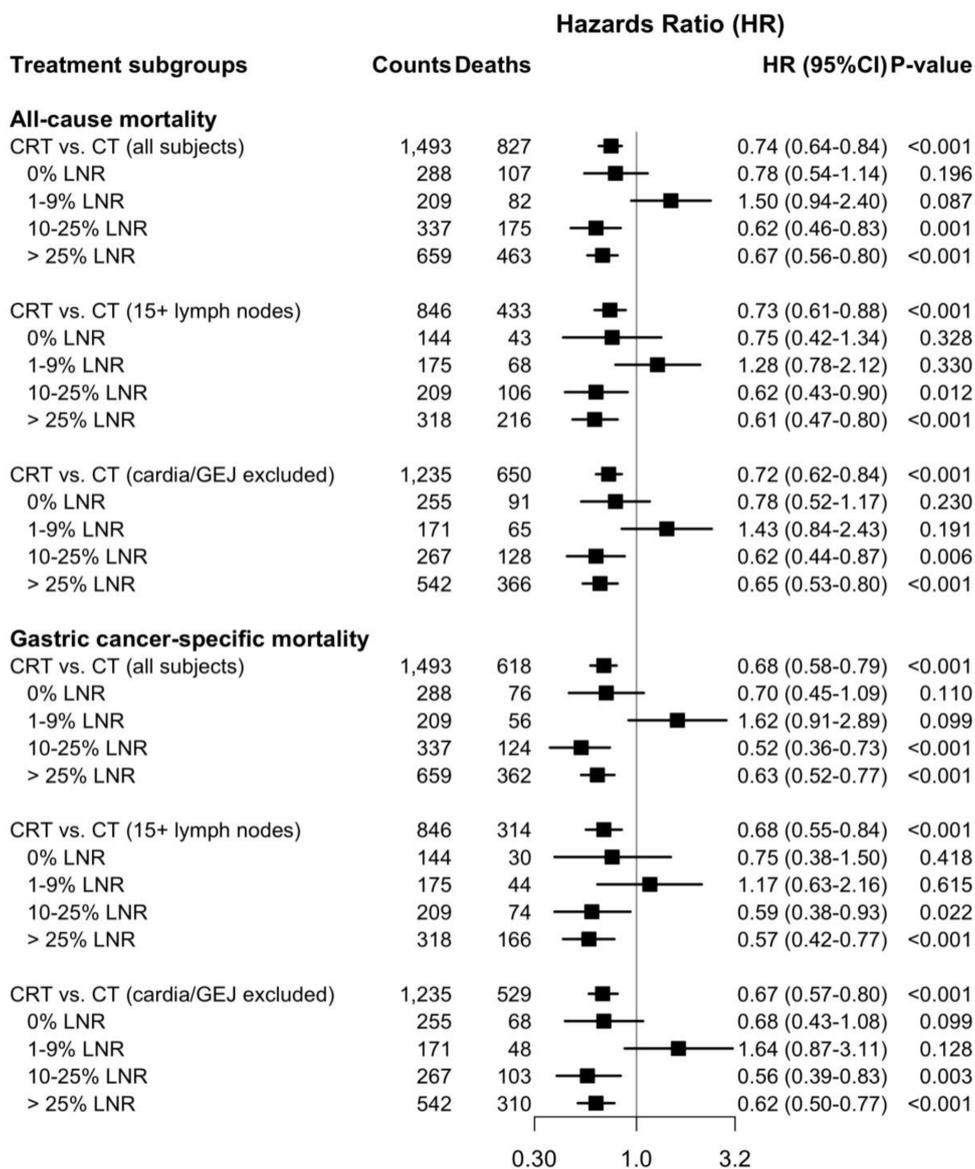

Figure 3 All-cause and gastric cancer-specific mortality hazards ratios for comparisons of adjuvant chemoradiotherapy (CRT) versus adjuvant chemotherapy (CT).

potential effects of selection bias. Results from the ARTIST trial, suggested that CRT may reduce the rate of locoregional recurrence compared to CT (7% vs. 13% P=0.0033) (27). Information about cancer recurrence is not available within the CCR for such a comparison and hence disease-free survival could not be reported. Additionally, information about chemotherapeutic agents and number of chemotherapy cycles administered was also not available. Hence, outcomes were analyzed based on receipt of treatment. Early discontinuation of assigned treatment could have certainly impacted the

outcomes and could not be accounted for.

Conclusions

Our study shows that LNR is an important and readily available tool that can aid adjuvant treatment decisions in patients with resected GC. CRT was associated with survival benefit compared to CT in patients with high LN disease burden (≥10% LNR) even after adequate lymphadenectomy with gastric resection. These results should be taken into

consideration when offering adjuvant treatment for patients with LN positive disease. In addition, future clinical trials should take into account this stratification when assigning treatments. In the near future, genotypic classification of GC will likely guide treatment decisions. Until then, available tumor phenotypic characteristics should be used to the fullest extent to best select patients for various treatment options.
