**Background:** Accurate staging plays a pivotal role in cancer care. The lymph node (LN) ratio (LNR) and the log odds of positive LNs (LODDS) have been suggested as alternatives to the N staging since the TNM system has the risk of stage migration. The prognostic significance of LNR and LODDS in young patients with gastric cancer (GC) has not been reported. This study aims to investigate the correlations between LNR and LODDS and survival of young patients with GC, and compare the predictive performance of these LN staging methods.

**Methods:** GC patients before the age of 40 from 2004 to 2016 in the Surveillance, Epidemiology and End Results database were enrolled. The prognostic evaluation of the N factor, LNR and LODDS was compared using the time-dependent receiver operating characteristic (ROC) analysis, area under the curve (AUC), C-index and Akaike information criterion (AIC).

**Results:** Multivariate survival analysis identified that the LNR and LODDS were significantly independent prognostic indicators for overall survival (OS) in young patients with GC and in the subgroups comprised of patients with  $\leq 15$  LNs examined. The time-dependent ROC curves of the LNR and LODDS were continuously superior to that of the N factor in predicting OS during the observation period. And the AUCs revealed that the predictive accuracy of the LNR and LODDS was remarkably superior to the N factor at 1 and 3 years ( $P < 0.05$ ). The model incorporating LNR or LODDS had higher C-index and lower AIC when comparing to the model incorporating the N factor.

**Conclusions:** The LNR and LODDS improve accuracy of survival risk prediction in young patients with GC when comparing to the N factor. These two novel LN classification methods should be considered as alternatives to the N staging for the prognostic prediction of young patients with GC.

**Keywords:** Young patients; gastric cancer (GC); lymph node ratio (LNR); log odds of positive lymph nodes; prognosis

## Introduction

Gastric cancer (GC) ranks as the fifth most frequent malignancy worldwide, and is the fourth main cause of cancer-related deaths (1). GC is generally considered to be an age-related disease. Although most GC patients are middle-aged and elderly, there has been reported a rising trend recently in young cases (2,3). The definitions of GC in young patients were quite inconsistent among studies. Most literatures defined young age as below 40 (4-7) or 45 years (8-10), while others used 30 (11,12), 50 (13,14), 60 (15) or even 70 (16). With different age criterion used, young subjects accounted for 2–31% of all GC cases (10,17-19). Accumulating studies have found that young patients with GC tended to have higher rates of female sex, and were more prone to have aggressive biological features, including diffuse or signet-ring histology, poorly differentiated lesions, advanced tumor stage, and frequent nodal involvement (6,9,20-22). Despite a favorable general condition, organ function and tolerance to treatment in young GC patients, a large proportion of them may have no alarm symptoms, contributing to delay in diagnosis and a poor clinical outcome. Young patients with GC face unique challenges including differences in tumor biological characteristics and variations in effectiveness and safety of treatment (9,23,24). Meanwhile, considerations about fertility preservation and early death need to be taken into in such special population. Thus, an effective and practical scoring system for accurate prognostic prediction and optimal treatment is of vital significance with respect to these patients.

Accurate staging plays a pivotal role in cancer care. It could reflect the extent of tumors, determine treatment options, predict prognosis, and enable different countries and institutions to compare patient cohorts. Currently, the American Joint Committee on Cancer (AJCC) TNM staging is the universally accepted system in cancer, which is based on the depth of the primary tumor invasion (T stage), the number of metastatic lymph nodes (N stage) and the status of distant metastasis (M stage) (25-27). However, the current existing TNM staging is subject to the risk of stage migration when using the N category (26,28-31). Stage migration, so-called *Will Rogers phenomenon*, refers to instances in which judgement of an insufficient count of lymph nodes (LNs) removed results in understaging and subsequent underestimation of disease severity (32). In GC, the AJCC staging system recommends that at least 15 LNs should be examined for an accurate estimation of N stage (26). To minimize the bias caused by an insufficient count of harvested LNs and stage migration, the lymph node ratio (LNR) (33-39) and the log odds of positive

LNs (LODDS) have been proposed (40,41). The former is calculated by dividing the count of metastatic LNs by the sum of examined LNs, while the latter is defined as the logarithm of the ratio between positive nodes and negative nodes. Extensive studies have reported superior predictive values of the LNR and LODDS when compared with the present N stage using only a metastatic LN count, and considered these two novel LN staging methods as alternatives to the N stage (33-41). However, findings for the role of the LNR and LODDS in young patients with GC have not been reported.

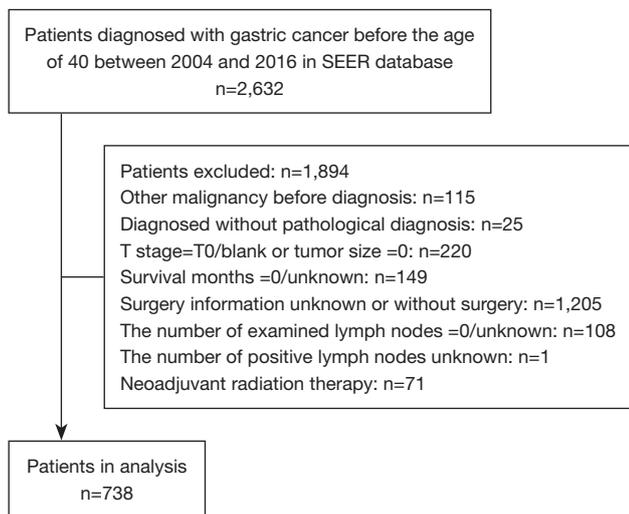

The Surveillance, Epidemiology, and End Results (SEER) database is an US National Cancer Institute's open-access public database with an annual update. It captures a wide variety of demographic and clinical data as well as data on treatment and survival from 18 established cancer registries covering about 34.6% of the US population. In this study, we aimed to investigate the correlations between different LN classification methods (AJCC N stage, LNR and LODDS) and survival of young patients with GC, and compare the predictive performance of these three LN staging methods through reviewing data obtained from the SEER dataset.

We present the following article in accordance with the STROBE reporting checklist (available at <https://dx.doi.org/10.21037/jgo-21-185>).

## Methods

### *Study population*

Our design was a population-based and retrospective study. In this study, GC in young patients was defined as that manifesting before 40 years old, as was indicated by previous studies (4-7). From 2004 to 2016, young patients with GC patients who were histologically proven diagnosed were included. We used the International Classification of Diseases for Oncology, 3rd Edition (ICD-O-3) to determine the tumor sites (C16.0-C16.6, C16.8, C16.9) and histological types (8010-8231, 8255-8576). The exclusion criteria were the following: (I) patients with record of previous malignant disease before being diagnosed with GC; (II) patients without histopathologic diagnosis or diagnosed only at autopsy or via death certificate; (III) patients without important clinicopathological information (tumor size =0 or T stage = T0/blank); (IV) patients with incomplete or inaccessible follow-up; (V) unknown surgery information or patients without surgery; (VI) zero or unknown examined lymph nodes; (VII) unknown positive lymph nodes; (VIII)

**Figure 1** Flowchart for selection procedure of young patients with gastric cancer from Surveillance, Epidemiology and End Results (SEER) database.

patients with neoadjuvant radiation therapy. SEER\*Stat software version 8.3.8 (<https://www.seer.cancer.gov/seerstat>) was applied to extract the data and construct the case listing. A total of 738 patients were included in the study. *Figure 1* showed the detailed workflow process for patient selection. The SEER database is an open-access cancer database that only contains de-identified patient data. Therefore, this study was exempted from the approval by the institutional review board of the First Affiliated Hospital of Sun Yat-sen University.

For each patient, the demographic characteristics (including age at diagnosis, race, gender, marital status and insurance), tumor and treatment features (including tumor location, grade, histology type, tumor size, the number of examined LNs, T stage, N stage, M stage, surgery, chemotherapy, and radiotherapy), and follow-up information (including survival status, survival time and cause of death) were acquired. Primary tumor sites in this study were classified into four categories: cardia (C16.0), middle site (C16.1, C16.2, C16.5, C16.6), distal site (C16.3, C16.4), as well as overlapping or not otherwise specified (NOS) (C16.8, C16.9). We divided histology types into three categories: diffuse type (8020, 8021, 8022, 8142, 8145, 8490), intestinal type (8140, 8144, 8210, 8211, 8260, 8480, 8481), and other type (8010, 8032, 8033, 8041, 8071, 8255, 8560, 8576). The final follow-up evaluation was conducted in December 31, 2016. The outcome in this study was overall survival (OS), defined as the period from the time

of initial diagnosis to the time of death from any cause or survive at last follow-up.

### *Definition of lymph node ratio and log odds of positive lymph nodes*

The LNR was calculated by dividing the count of positive LNs by the sum of corresponding examined LNs in the SEER database. The LODDS was defined as  $\log_{10}[(\text{positive LNs}+0.5)/(\text{negative LNs}+0.5)]$ . We added 0.5 to both the denominator and the numerator to avoid singularity. Although the SEER program recorded the types of gastrectomy performed on some patients, such as total or subtotal/partial gastrectomy, there were still quite a few cases without detailed types of gastric resection. What we could obtain from the SEER was the sum of lymph nodes which were removed and examined by the pathologist (the examined LNs), as well as the exact number of lymph nodes that had metastasized (the positive LNs). In this study, the optimal cutoff levels for LNR and LODDS were 0.36 and  $-0.28$ , respectively, which were derived using X-tile software (Yale University, New Haven, CT, USA) (42). All the patients were further categorized into the pathologically negative lymph node metastasis group (N0, pN $-$ ) and pathologically positive lymph node metastasis group (N1-3, pN $+$ ), the low LNR ( $\leq 0.36$ , L-LNR) group and the high LNR ( $> 0.36$ , H-LNR) group, the low LODDS ( $\leq -0.28$ , L-LODDS) group and the high LODDS ( $> -0.28$ , H-LODDS) group.

### *Statistical analysis*

Continuous variables were presented as medians and interquartile ranges (IQR), while categorical variables were presented as the number and the percentage (N, %). Correlations between continuous variables were assessed via the Kruskal-Wallis analysis, and categorical variables were analyzed using the Chi-square or Fisher's exact test. Survival curves were plotted using Kaplan-Meier method and analyzed by log-rank test. Univariate and multivariate survival analyses were conducted using the Cox proportional hazards regression model. The hazard ratios (HRs) and 95% confidence intervals (CIs) were shown. Variables that obviously influenced survival in univariate analysis were entered into multivariate analysis to identify prognostic indicators. The predictive performance of AJCC N factor, LNR and LODDS were assessed by time-dependent receiver operating characteristic (ROC) curves (43,44) and

area under the curve (AUC). The Harrell's concordance index (C-index) and Akaike information criterion (AIC) were calculated to identify the predictive accuracy and discriminating superiority of different multivariate prediction models incorporating AJCC N factor, LNR and LODDS, respectively. A higher C-index and a lower AIC indicated a better predictive accuracy. Statistical analyses were performed using SPSS software version 20.0 (Chicago, IL, USA) and R software version 3.6.1 (<https://www.r-project.org/>). All analyses were two-tailed, and statistical significant levels were set at P-value <0.05.

The study was conducted in accordance with the Declaration of Helsinki (as revised in 2013).

## Results

### *Clinicopathological characteristics*

Totally, 738 young patients with pathologically confirmed GC were eligible for the final analysis. The median age of the all cases was 36 years (IQR: 32–39 years), 47.7% of the patients were men (N=352), 52.3% were women (N=386). Caucasians accounted for a large proportion of the cohort (65.1%, N=480), and more than half of patients were married (59.0%, N=435). 80.7% of the tumors were poorly differentiated (N=595), and the most common histology type was diffuse (59.2%, N=437). The median number of examined LNs was 17 (IQR: 11–27 LNs), 43.5% of the patients were with 15 or fewer examined LNs (N=321), 56.5% were with 16 or more examined LNs (N=417). *Table 1* showed the demographic and clinicopathological features of the study cohort.

### *Clinicopathological findings*

The correlations between clinicopathological factors and the AJCC N factor, LNR, and LODDS were listed in *Table 1*. There were 207 patients (28.0%) in the pN– group and 531 patients (72.0%) in the pN+ group, 452 patients (61.2%) in the L-LNR group and 286 (38.8%) patients in the H-LNR group, 442 patients (59.9%) in the L-LODDS group and 296 patients (40.1%) in the H-LODDS group. The positive LN metastasis and increased LNR and LODDS were significantly correlated with insurance (P=0.006, P=0.001, P=0.001), a higher degree of differentiated type (P<0.001, P=0.047, P=0.022), a larger tumor size (all P<0.001), an advanced T stage (all P<0.001), distant metastasis (all P<0.001), and administration of chemotherapy (P<0.001,

P=0.001, P=0.001). The positive LN metastasis showed a significant correlation with the marital status (P=0.004) and administration of radiotherapy (P<0.001). The increased LNR and LODDS were correlated with tumor subsites (P<0.001, P=0.002).

The positive LN metastasis was correlated with a higher number of total LNs examined (P<0.001), while the increased LNR and LODDS showed significant correlations with a lower number of total LNs examined (P=0.001, P=0.001). Furthermore, the AJCC N factor showed a significant correlation (P<0.001) when the all patients were divided into either the ≤15 total LNs group or the >15 total LNs group, yet LNR and LODDS showed no remarkable differences.

### *Survival analysis*

The median survival time was 29 months, while that of the quartile was 12–68 months. Among the 738 young patients with GC, 403 (54.6%) succumbed to all causes of death, including 380 patients (51.5%) who had cancer-specific death and 23 (3.1%) who died from non-cancer-related causes.

The influences of the three different LN staging methods on OS of the study cohort were presented in *Figure 2* using the Kaplan-Meier method. The 5-year OS rates for pN– group were 0.769, 0.305 for pN+ group, with a remarkable distinction (P<0.001) (*Figure 2A*). The 5-year OS rates for L-LNR group were 0.598, 0.179 for H-LNR group, with a statistical difference (P<0.001) (*Figure 2B*). Similarly, the 5-year OS rates for L-LODDS group were 0.613, 0.175 for H-LODDS group, with a statistically prominent difference (P<0.001) (*Figure 2C*).

Univariate survival analysis identified a series of factors including the race, tumor subsites, tumor size, T stage, AJCC N factor, LNR, LODDS, M stage, together with chemotherapy to be predictors for OS (*Table 2*). The variables that remarkably influenced survival in univariate analysis were investigated using the Cox regression model for multivariate analysis. Multivariate analysis demonstrated that the N factor (HR =1.766, 95% CI: 1.274–2.449, P=0.001), LNR (HR =1.886, 95% CI: 1.518–2.342, P<0.001) and LODDS (HR =1.939, 95% CI: 1.559–2.410, P<0.001) were independent prognostic indicators.

### *Time-dependent ROC curve analysis*

The time-dependent ROC curves were constructed to

AUC, area under the curve; LNR, lymph node ratio; LODDS, the log odds of positive lymph nodes; CI, confidence interval; LN, lymph node. \*indicate significant P values.  $^\dagger$ ,  $P_1$  value: AUC of AJCC N factor vs. AUC of LNR.  $^\ddagger$ ,  $P_2$  value: AUC of AJCC N factor vs. AUC of LODDS.

quantify the predictive accuracy of the AJCC N factor, LNR and LODDS, and to compare their sequential trends on hazard ratios for OS. In the group including all young GC patients, the time-dependent ROC curves of both the LNR and the LODDS were generally continuously superior to that of the N factor in predicting the survival (Figure 3A). Additionally, the AUCs generated for survival status at 1 and 3 years for the LNR and LODDS were significantly superior to that of the N factor (AUC values: LNR: 0.694 and 0.698,

LODDS: 0.703 and 0.701, N factor: 0.628 and 0.657, respectively), with a statistical difference (at 1 year: LNR vs. N factor:  $P < 0.001$ , LODDS vs. N factor:  $P < 0.001$ ; at 3 years: LNR vs. N factor:  $P = 0.030$ , LODDS vs. N factor:  $P = 0.019$ ) (Table 3). However, at 5 and 10 years, the AUCs for the LNR were 0.694 and 0.666, 0.707 and 0.677 for the LODDS, 0.682 and 0.672 for the N factor, with  $P > 0.05$  (Table 3), indicating that the predictive accuracy of these three LN staging methods at 5 and 10 years was comparable.

**Figure 4** Kaplan-Meier analysis for overall survival of young gastric cancer patients with  $\leq 15$  examined lymph nodes in the negative and positive lymph node metastasis groups (A), low and high lymph node ratio groups (B), and low and high log odds of positive lymph nodes groups (C). The AJCC N factor, LNR and LODDS were significantly associated with overall survival (all  $P < 0.001$ ). LNR, lymph node ratio; LODDS, log odds of positive lymph nodes.

### Comparisons among the three multivariate models

The C-index, AIC and likelihood ratio  $\chi^2$  scores were used to compare the distinguishing abilities of multivariate model 1 (T stage, N factor and M stage), multivariate model 2 (T stage, LNR and M stage) and multivariate model 3 (T stage, LODDS and M stage), and to identify a superior multivariate prediction model (Table 4). In an analysis including all young GC patients, the C-index values in the model 2 (0.783, 95% CI: 0.759–0.806) and model 3 (0.783, 95% CI: 0.760–0.807) significantly increased when comparing with the model 1 (0.774, 95% CI: 0.749–0.799) (model 2 *vs.* model 1:  $P = 0.042$ , model 3 *vs.* model 1:  $P = 0.034$ ). Furthermore, the AIC values in the model 2 (4,584.90) and model 3 (4,582.39) were smaller than that in the model 1 (4,614.48). These results indicated that incorporating the LNR or LODDS into the multivariate model could enable a superior prediction model for survival in young patients with GC.

### Overall survival in patients with 15 or fewer examined lymph nodes

Kaplan-Meier curves of OS based on the N factor, LNR and LODDS in young GC patients with 15 or fewer examined LNs were shown in Figure 4. Three LN staging methods were significantly correlated with OS (all  $P < 0.001$ ). In a multivariate analysis for OS, the AJCC N factor (HR = 1.690, 95% CI: 1.115–2.562,  $P = 0.013$ ), LNR (HR = 1.424, 95% CI: 1.019–1.990,  $P = 0.038$ ) and LODDS (HR = 1.397, 95% CI: 1.002–1.949,  $P = 0.049$ ) were significantly

independent prognostic factors in these patients (Table S1). In the subgroup including patients with  $\leq 15$  LNs examined, although the time-dependent ROC curve of the N factor was continuously superior to that of the LNR and LODDS in predicting the survival after 5 years (Figure 3B), the AUC values among these three LN staging methods were not statistically different ( $P > 0.05$ ) (Table 3).

In an analysis including the population of patients with  $\leq 15$  LNs examined, the AIC values in the multivariate model 1, 2 and 3 were 1,782.58, 1,786.92 and 1,786.36, respectively (Table 4). The C-index in the model 1, 2 and 3 were 0.787 (95% CI: 0.752–0.822), 0.784 (95% CI: 0.749–0.820) and 0.785 (95% CI: 0.749–0.820), respectively. The multivariate model 1 had a slightly increased C-index, but no significant differences were found when comparing to the model 2 and 3 (model 2 *vs.* model 1:  $P = 0.331$ , model 3 *vs.* model 1:  $P = 0.354$ ).

### Discussion

Recently, several lines of findings have reported an increasing trend in the incidence of GC patients in young age (2,3,13,45). GC in the young has a more aggressive growth pattern and carries a worse clinical outcome compared with older individuals (6,9,20–22). An effective and well practical prediction model is urgently required for prognosis estimation and guidance in such separate entity. AJCC TNM staging is the most widely reliable and accepted system in GC, but it is subject to the risk of stage migration when using the N classification. Accurate staging

plays a pivotal role in cancer care. In the present study, we evaluated the prognostic abilities of the three LN staging systems including AJCC N factor, LNR and LODDS in young patients with GC. To our knowledge, no study before has compared the predictive value of the ratio-based nodal staging, LNR and LODDS, with the number-based N category in such special population. We demonstrated that the ratio-based nodal staging, LNR and LODDS, were remarkable prognosticators for survival in the young GC patients and in the population of patients with  $\leq 15$  LNs examined. Although AJCC N factor was also an independent risk factor in our study cohort, it was observed a significant correlation when patients were divided into two subgroups according to whether total LNs examined  $\leq 15$  or not, and might lead to stage migration. Additionally, the multivariate prediction models incorporating the LNR or LODDS had higher C-index and lower AIC when comparing to the model incorporating the N factor, suggesting uses of LNR and LODDS as alternatives to the N factor for the prognostic prediction of young patients with GC.

Lymph node metastasis is the most frequent mode of tumor metastasis in GC, and thus lymph node dissection plays a crucial role in GC surgery for staging and treatment options (26,46). The pathological assessment of LNs in the 8th edition of AJCC TNM staging system is on the basis of the absolute count of positive LNs, and its predictive efficacy for prognosis is significantly influenced by the extent of LN dissection (28-31,47). A study from Smith *et al.* using SEER data between 1973 and 1999

found a therapeutic benefit of a large number of examined LNs (30). According to the TNM staging, at least 15 harvested LNs is essential for accurate estimates of N category. A poor primary LN count could produce stage migration, compromise a correct staging and subsequently underestimate the severity of disease (28,29,31,48). 10–15% of patients were found the phenomenon of stage migration when using the N classification (29-32,38). To reduce the potential bias caused by an insufficient number of harvested LNs and stage migration, the LNR, namely, the ratio between positive and examined LNs, has been proposed for ameliorating the understaging of diagnosis and more accurately assessing the disease severity. The LNR is less influenced by the total number of harvested LNs. Extensive studies have reported that the LNR, rather than the existing AJCC N staging, could compensate for the stage migration effect and had a better predictive value in GC patients, suggesting it to be considered as an alternative to the N classification in patients with adequate or inadequate LNs examined (33-39,49,50). However, the LNR also has its flaws in failing to stratify the prognosis of patients with no metastatic (LNR =0) or all metastatic (LNR =1) LNs. These flaws contributed to the creation of the LODDS, which is defined as the log value of the ratio between positive nodes and negative nodes (40,41). The LODDS, using a base number and negative nodes as the denominator, carries all the auxiliary information of the LNR, and therefore it could further distinguish those patients with either very high or low LNR. Spolverato *et al.* observed that when the LN status was modeled as a continuous variable, the

LODDS was the best predictor of survival (51). However, the LODDS might lost its predictive value and the LNR became the best predictor when the LN status was categorized.

In the present study, we found that the three different LN staging methods, AJCC N factor, LNR and LODDS, were significantly independent prognostic factors for OS in the cohort including all young GC patients and in the subgroups comprised of patients with  $\leq 15$  LNs examined. However, correlation analysis between clinicopathological characteristics and there different LN staging methods observed a significant correlation in the AJCC N factor ( $P < 0.001$ ) when patients were divided into two subgroups according to whether total LNs examined  $\leq 15$  or not, indicating that there might exist stage migration. Moreover, the time-dependent ROC curves of the LNR and LODDS were continuously superior to that of the N factor in predicting OS during the observation period. And the AUCs also revealed that the predictive accuracy of the LNR and LODDS was remarkably superior to the N factor at 1 and 3 years. In addition, the multivariate models incorporating the LNR or LODDS had higher C-index values and lower AIC values when comparing to the model incorporating the N factor, suggesting that the LNR and LODDS could be considered as alternatives to the N factor for prognostic prediction in young patients with GC. In patients with  $\leq 15$  examined nodes, the prognostic power of the three LN classification methods was comparable.

Although the present study enabled us to distinguish a better LN staging method for predicting prognosis of young GC patients, we did not investigate the effect of neoadjuvant therapy on the nodal status. Currently, in the west, it is recommended that GC be treated in a multimodal fashion and surgical treatment should be preceded by neoadjuvant (perioperative) chemotherapy. An analysis of pathologic tumor response and nodal status in the Perioperative Chemotherapy versus Surgery Alone for Resectable Gastroesophageal Cancer (MAGIC) trial demonstrated that neoadjuvant chemotherapy with a regimen of epirubicin, cisplatin, and fluorouracil decreased tumor size and stage and significantly improved survival (52). Moreover, a recent study based on the MAGIC trial found that the LN metastases and not the regression of the primary tumor was the primary arbiter of survival after chemotherapy plus resection (53). Tumor diameter and depth of infiltration, Lauren histological subtype, and tumor regression grading may reflect the impact of neoadjuvant therapy on LN status (54). A study from Roland *et al.*

focus on the effect of neoadjuvant therapy on the LNR in pancreatic cancer and showed that the LNR might serve as a better prognostic parameter following neoadjuvant therapy than standard N0 or N1 annotation (55). Similarly, neoadjuvant therapy in rectal cancer did not affect LNR despite reduced LN retrieval and therefore LNR might be a more reliable prognosticator than LN retrieval (56). In this study, patients who received neoadjuvant therapy/radiotherapy were excluded from the analysis. Even though our study's most noticeable findings shed light on clinical advantage of the LNR and LODDS over the N classification in young patients with GC, the results may not be applicable to all patients, especially those with resectable GC undergoing neoadjuvant therapy.

This study has several limitations. Firstly, this study was retrospective and potential bias might have led to in the data selection process. Secondly, it was a population-based study capturing data from national registry, but the detailed information on therapy and outcomes were limited in the SEER database. Apart from OS, other clinical outcomes such as quality of life, distant control, local control were not recorded. Information about type of gastrectomy, systemic therapy, specialized regimens and measurement of response to treatment were also absent, which could influence the detailed real-world outcomes for young patients with GC and the prognostic power of the LNR and LODDS to some extent. Thirdly, there was no consensus regarding the cutoffs for the LNR and LODDS even though different cutoff values had been proposed. Here we determined the LNR and LODDS cutoffs of 0.36 and  $-0.28$ , respectively, and found the LNR and LODDS to be the independent prognostic factors. The results of this study may not be appropriate for other studies. The most optimal cutoffs for young patients with GC should be further investigated. Finally, we did not verify the results in our own patients. Further external validation such as enrolling our own patients is warranted to extend the extrapolation of the reported results. And additional prospective multicenter studies are also necessary.

Despite these limitations, the present study also has many strengths. To our knowledge, it is the first comparing the predictive value of the ratio-based nodal staging, LNR and LODDS, and the number-based N classification in young patients with GC, such a special population. The findings of our study are intuitive, convenient to use and well-timed. An accurate staging is indeed of great significance for determining the suitable therapeutic schedule and follow-up scheme for every stage of the disease. Even though the current AJCC

TNM staging is the most widely used system, it also has its deficiency especially in the population of patients with an insufficient number of harvested LNs. Findings from our study detected clinical advantage of the LNR and LODDS over the N classification. These results may be regarded as a basis for prospective researches and affect the clinical treatment options for young patients with GC.

## Conclusions

In conclusion, the current study demonstrated that the LNR and LODDS were significant independent prognostic indicators for OS in young patients with GC. The predictive performance of the LNR and LODDS were superior to that of the AJCC N factor, suggesting that the LNR and LODDS could improve accuracy of survival risk prediction and should be considered as alternatives to the AJCC N factor for the prognostic prediction of young patients with GC.

## Acknowledgments

We thank all staff of the SEER program for the creation of the SEER database.

*Funding:* This study was supported by Guangzhou Science and Technology Development Funds (Key Program, No. 201803010103).
